Average causal effect

Introduction

- Let A denote the binary treatment (A = 1 for treatment and 0 otherwise).
- Let Y denote the binary outcome (Y = 1 for event and 0 otherwise).
- Let $Z = (Z_1, Z_2, ..., Z_k)$ denote the set of the k baseline covariates.
- Let Y(1) and Y(0) be the two potential outcomes under the treatment and the control, respectively.
- The average causal effect is :

$$ACE = E[Y(1) - Y(0)]$$

It represents the mean difference between the outcomes of individuals if they
had been treated or untreated.

UNIVERSITE DE NANTES

Three categories of methods for estimating the ACE

- The regression of the treatment allocation to obtain propensity scores (PS):
 - Inverse Probability Weighting (IPW)
 - Full matching (FM)
 - Ftc.
- The regression of the outcome for G-computation (GC)
- The targeted maximum likelihood estimator (TMLE) as a doubly robust estimation which combines the outcome and treatment regressions
- Ftc.

Introduction 00000

4/22

Literature related to GC is less prolific compared to PS-based methods

- Suppose (Y_i, A_i, Z_i) a dataset of n independent realisations of (Y, A, Z).
- The first step of GC is to fit f(Y|A, Z)
- This outcome model is frequently referred to the Q-model.
- The second step consists in predicting the two potential outcomes for each individual $i: \hat{Y}_i(1) = \hat{f}(Y|1, Z_i)$ and $\hat{Y}_i(0) = \hat{f}(Y|0, Z_i)$
- The average causal effect is then estimated by

$$A\hat{C}E = n^{-1} \sum_{i} \left[\hat{Y}_{i}(1) - \hat{Y}_{i}(0) \right]$$

Introduction

Three simulation-based were performed in the context of binary outcome and binary treatment

- Which covariates should be considered in GC (true confounders, those causing the outcome, etc.)?
- What is the robustness of GC to a near-violation of the positivity assumption?
- $oldsymbol{0}$ What are the performances of GC associated with machine learning (ML)?

Introduction

Plan

- Introduction
- 2 Covariates to consider in GC
- **3** GG with positivity near-violation
- **4** GC with Machine Learning
- Conclusions

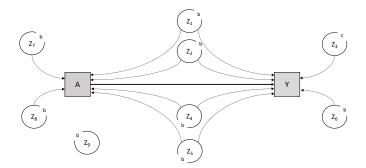

Covariates to consider in GC GG with positivity near-violation GC with Machine Learning Conclusion:

○●○○ ○○○○ ○○○○ ○○○○

Simulated data

- 4 sample sizes (n = 100, 300, 500, 2000)
- 2 treatment effect $(H_1 \text{ versus } H_0)$

8/22

Compared methods

We compared several methods (all based on logistic regression) :

- GC : variance obtained by parametric simulations.
- IPTW : stabilized weights and robust sandwich-type variance estimator.
- FM: robust sandwich-type variance estimator.
- TMLE : variance obtained by efficient influence curve.

We compared different sets of covariates :

- those causing outcome $(Z_1, Z_2, Z_3, Z_4, Z_5, Z_6)$.
- those causing treatment $(Z_1, Z_2, Z_4, Z_5, Z_7, Z_8)$.
- those causing outcome and treatment (true confounders : Z_1, Z_2, Z_4, Z_5).
- all the covariates.

- No bias for GC, IPTW, TMLE.
- The highest power was for GC with the covariates causing outcome. UNIVERSITÉ DE NANTES

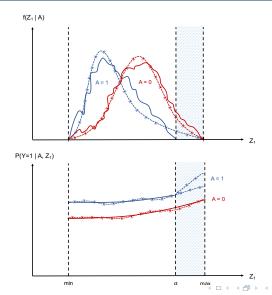

Plan

- Introduction
- 2 Covariates to consider in GC
- 3 GG with positivity near-violation
- **4** GC with Machine Learning
- 6 Conclusions

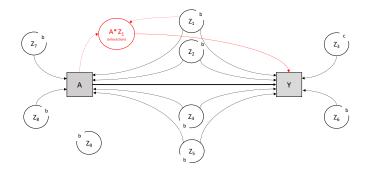

Extrapolation issue from the Q-model

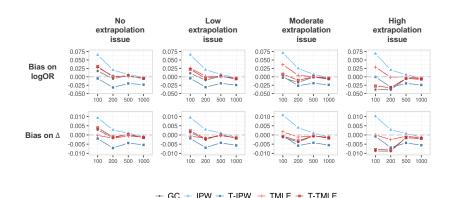

Simulated data

- Z_1 was generated with a 10% prevalence. The near-violation concerned :
 - 0% of the datasets for n > 500.
 - 1.3% for *n* = 200 subjects.
 - 14.1% for n = 100 subjects.
- The extrapolation issue was proportional to the interaction level.

Results

- T-IPW and T-TMLE are the truncated IPW and TMLE with bounds at the 10th and 90th percentiles.
- GC and TMLE were the most robust methods

UNIVERSITÉ DE NANTES

only high extrapolation issue lead to substantial bias.

Plan

- Introduction
- 2 Covariates to consider in GC
- 3 GG with positivity near-violation
- **4** GC with Machine Learning
- 6 Conclusions

Method: a super learner (SL) applicable in practice with small sample size and computation time

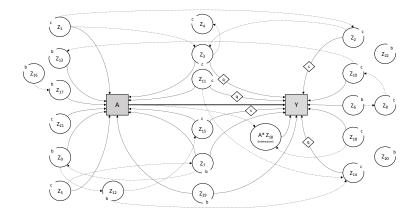

- The SL consists in averaging the predictions obtained from the four approaches:
 - Lasso logistic regression. A was forced. All the possible interactions between A and covariates Z were tested. B-splines for the quantitative covariates Z.
 - Elasticnet logistic regression with similar assumptions.
 - Neural network with one hidden layer.
 - Support vector machine with a radial basis function kernel.
- The tunning parameters and the weights were obtained by maximizing the average AUC of a ten-fold cross-validation.
- The variance was obtained by bootstrap cross validation.
- The tuning parameters being estimated once on the entire sample.

Simulated data

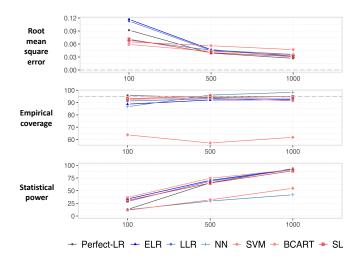

Results in terms of Mean Bias (MB).

Results in terms of power

Plan

- Introduction
- 2 Covariates to consider in GC
- **3** GG with positivity near-violation
- **4** GC with Machine Learning
- 6 Conclusions

Conclusions

The main advantages of the GC:

- The GC is simple to implement.
- The GC is a powerful method, especially when considering the covariates causing the outcome.
- The GC is quite robust to the positivity near violation, except for high extrapolation issues.
- The proposed SL allows to prevent the Q-model misspecification.
- The automatic algorithm allows bootstrapping the entire estimation procedure, including the Q-model construction, in the variance estimation.

The main limitation of the GC:

• It does not constitute a doubly robust estimator.

Conclusions
